

Solutions to CS/MCS 401 Exercise Set #4 (Summer 2007)

Exercise 8.1-1 The minimum depth of a leaf node is $n-1$, as every comparison sorting algorithm requires at least $n-1$ comparisons, even in the best case. Suppose the sorted order for an array a of size n is $a[i_1], a[i_2], a[i_3], \dots, a[i_{n-1}], a[i_n]$.

The sorting algorithm must compare $a[i_1]$ with $a[i_2]$; otherwise it has no way to distinguish the order

$$a[i_1], a[i_2], a[i_3], \dots, a[i_{n-1}], a[i_n]$$

from

$$a[i_2], a[i_1], a[i_3], \dots, a[i_{n-1}], a[i_n],$$

since every comparison other than that of $a[i_1]$ with $a[i_2]$ turns out the same in both cases.

Likewise, it must compare $a[i_2]$ with $a[i_3]$, ..., $a[i_{n-1}]$ with $a[i_n]$.

Exercise 8.1-3 Suppose a comparison sorting algorithm runs in linear time from some fraction $\delta(n)$ of its inputs. This means that there exists a constant C (not depending on n) such that, for all n sufficiently large, the algorithm performs at most Cn comparisons for $\delta(n)n!$ of its $n!$ inputs. In the decision tree, there must be at least $\delta(n)n!$ leaves at depth Cn or less. But we know that the number of leaves at depth Cn or less is bounded by 2^{Cn} . So $\delta(n)n! \leq 2^{Cn}$, or $\delta(n) \leq 2^{Cn}/n!$. Approximating $n!$ by Stirling's formula gives

$$\delta(n) \leq 2^{Cn}/n! \leq 2^{Cn}/((n/e)^n \text{sqrt}(2\pi n)) = (2^C e/n)^n / \text{sqrt}(2\pi n).$$

Exercise 8.1-3 asks specifically about the case $\delta(n) = 1/2$, $\delta(n) = 1/n$, and $\delta(n) = 1/2^n$.

In none of these cases is $\delta(n) \leq (2^C e/n)^n / \text{sqrt}(2\pi n)$ for some constant C and all n sufficiently large. If $\delta(n) = 1/2^n$, then $\delta(n)/((2^C e/n)^n / \text{sqrt}(2\pi n)) = (n/2^{1+C} e)^n \text{sqrt}(2\pi n)$ approaches ∞ as n approaches ∞ , since $n/2^{1+C} e > 1$ for all n sufficiently large. So a comparison sorting algorithm cannot run in linear time even for $1/2^n$ of its inputs.

partition()
 returns *left+5*

Exercise J

Consider first the general case in which the pivot is chosen as the median of k elements, where k is odd and $k > 1$. We also assume $n \gg k^2$, so we may approximate choice of k distinct elements by choice of k elements with repetition allowed.

Let $A_S = \{a[i] \mid a[i] < n/4^{\text{th}} \text{ smallest element of } a\}$, and let $A_L = \{a[i] \mid a[i] > n/4^{\text{th}} \text{ largest element of } a\}$. In general, the probability that among k randomly chosen elements of a exactly i lie in an $n/4$ element subset of a is very close to $C(k, i)(1/4)^i(3/4)^{k-i}$, since n is large. In order to obtain a bad split, at least $(k+1)/2$ elements from our k -element subset must lie in A_S , or at least $(k+1)/2$ must lie in A_L . Each of these alternatives occurs with probability

$$\sum_{i=(k+1)/2}^k C(k, i)(1/4)^i(3/4)^{k-i},$$

so the probability of a bad split is twice this, or

$$\sum_{i=(k+1)/2}^k 2C(k, i)(1/4)^i(3/4)^{k-i},$$

For $k = 1, 3, 5$, and 7 , this evaluates as followed:

$$k = 1: \quad 1/2 = \mathbf{0.500}$$

$$k = 3: \quad 2 \cdot 3(1/16)(3/4) + 2 \cdot 1(1/64) = 20/64 = \mathbf{0.312}$$

$$k = 5: \quad 2 \cdot 10(1/64)(9/16) + 2 \cdot 5(1/256)(3/4) + 2 \cdot 1(1/1024) = 212/1024 = \mathbf{0.207}$$

$$k = 7: \quad 2 \cdot 35(1/256)(27/64) + 2 \cdot 21(1/1024)(9/16) + 2 \cdot 7(1/4096)(3/4) + 2 \cdot 1(1/16384) = \mathbf{0.139}.$$

Exer 9.3-1

Let us consider the general case where the input elements are divided into groups of q elements each, where q is odd. For simplicity, assume n is a multiple of q , so the number of groups is n/q . Let $T_q(n)$ be the time to find k^{th} smallest element. In class and in the text, $q = 5$ was used. For a fixed q , the *Select()* algorithm uses constant time to sort (or at least to find the median of) each group of q elements, and hence time linear in n to sort all q -element groups. (However, the constant multiplying n does increase as q increases.) Then *Select()* invokes itself recursively to find the median of the n/q medians, requiring time $T(n/q)$. Next *Select()* invokes *partition()*, modified to used the median of the n/q medians as the pivot. This takes linear time, and produces a split in which at least $(q+1)/2 \cdot n/2q - 1$ of the n elements are less than the pivot, and at least this number are greater. Ignoring the -1 , the fraction of elements on either side of the pivot is at least $(q+1)/(4q)$, meaning that the fraction on either side of the pivot can be at most $1 - (q+1)/(4q) = (3q-1)/(4q)$. The time for the recursive call to *Select()* on the left or right subarray is at most $T((3q-1)/(4q) \cdot n)$. So our recurrence for the running time is

$$T(n) = T(n/q) + T((3q-1)/(4q) \cdot n) + \Theta(n).$$

The sum of the subproblem sizes is $n/q + (3q-1)/(4q) \cdot n + \Theta(n) = 3(q+1)/4q \cdot n$. We showed in class that the solution was $\Theta(n)$ when $q = 5$; the proof relied only on the fact that the sum of the subproblem sizes was at most cn for some constant c less than 1. On the other hand, if the subproblems have size αn and βn with $\alpha + \beta = 1$, the solution is $\Theta(n \lg(n))$. (We proved this in class for $\alpha = 2/3$, $\beta = 1/3$, but the proof works for any α and β with $\alpha < 1$, $\beta <$

1, and $\alpha + \beta = 1$. So for *Select()* to run in linear time in the worst case, we need $3(q+1)/4q < 1$, or $3(q+1) < 4q$, or $q > 3$.

Thus, with groups of 3, the worst-case running time of *Select()* is not linear, but with groups of 5, 7, or any other odd integer it is linear.

Exer 9.3-8

First note: Let S be any set. If, for some q with $q < |S|/2$, we remove from S both q elements less than or equal to the (old) median of S and q elements greater than or equal to the median, then the median of S remains unchanged.

To keep things simple, let us assume $n = 2^k - 1$ for some k .

If $k = 1$, then we are finding the median of two elements; simply choose the smaller (for the lower median).

If $k > 1$, then $n \geq 3$. Let $m = (n+1)/2 = 2^{k-1}$, the middle position of X and Y . Since X and Y are sorted, the medians of X and Y are $X[m]$ and $Y[m]$, respectively. If $X[m] = Y[m]$, we are done; $X[m]$ is the median of the two arrays combined. If $X[m] < Y[m]$, then

$$X[m] \leq (\text{combined median}) \leq Y[m].$$

We may discard $X[1..m]$ (m elements \leq combined median) and $Y[m..n]$ (m elements \geq the combined median). This leaves two sorted subarrays, $X[m+1..n]$ and $Y[1..m-1]$ with $2^{k-1} - 1$ each, which have the same combined median as the two original arrays, so we can invoke our algorithm recursively to find the median of these two subarrays. Similarly, if

```
// Invoke initially as median( X, 1, n, Y, 1, n). T is the element type of X and Y. Note
// this code assumes for simplicity that n is one less than a power of 2. Note at all times
// xRight-xLeft = yRight-yLeft.
```

```
T median( T[] X, int xLeft, int xRight, T[] Y, int yLeft, int yRight)
    if ( xLeft == xRight )
        return min( X[xLeft], Y[yLeft] );
    xMid = (xLeft + xRight) / 2;
    yMid = (yLeft + yRight) / 2;
    if ( X[xMid] < Y[yMid] )
        return median( X, xMid+1, xRight, Y, yLeft, yMid-1 );
    else if ( X[xMid] > Y[yMid] )
        return median( X, xLeft, xMid-1, Y, yMid+1, yRight );
    else
        return X[xMid];
```
